

# 1 Nondimensional equations

The nondimensional system of equations we solve is

$$\nabla \cdot \mathbf{u} = 0 \quad (1)$$

$$\partial_t \mathbf{u} + \mathbf{u} \cdot \nabla \mathbf{u} = -\nabla \varpi + T \hat{z} + \text{Re}_0^{-1} \nabla^2 \mathbf{u} \quad (2)$$

$$\partial_t T + \mathbf{u} \cdot \nabla T + w \nabla_{\text{ad}} = \text{Pe}_0^{-1} \nabla^2 T' + \nabla \cdot [k \nabla \overline{T}] + Q \quad (3)$$

These are just the Boussinesq equations of motion, with some slight tweaks:

1. There is a nonzero adiabatic temperature gradient,  $\partial_z T_{\text{ad}} = -\nabla_{\text{ad}}$ . We choose this sign convention ( $\nabla_{\text{ad}}$  and similarly  $\nabla_{\text{rad}}$  will be positive) to align better with the stellar structure community's intuition.  $|\nabla T_0|$  and  $\nabla_{\text{ad}}$  may be much larger in magnitude than the convective fluctuations. The background temperature field  $T_0$  does not enter into the momentum equation, as it is automatically canceled by a background  $\nabla \varpi$ .
2. Convection is driven by internal heating,  $Q$ . I've confirmed with some simple tests that  $|u|^2 \approx Q$ , and therefore the convective frequency is  $f_{\text{conv}}^2 \approx Q$ .
3. The control freefall Péclet number,  $\text{Pe}_0$ , and the diffusivity associated with it, only acts on fluctuations, not on the  $k_x = 0$  mode. For the  $k_x = 0$  mode, we model the radiative flux as  $F_{\text{rad}} = -k \nabla \overline{T}$ , where  $k$  is a nonconstant coefficient,  $k(z)$ .  $k$  may be a larger or smaller diffusivity than  $\text{Pe}_0^{-1}$ , and its magnitude is set by  $\int Q dz \approx -k \nabla \overline{T}$ .

## 2 Model Setup

We will study a two-layer model in  $z = [0, L_z]$  in which the conductivity,  $k(z)$  is a step function such that

$$k(z) = \begin{cases} k_b & z < L_{\text{cz}} \\ k_t & z \geq L_{\text{cz}} \end{cases} \quad (4)$$

where subscript “t” refers to the top layer and “b” refers to the bottom. Generally, we will set  $L_{cz} = 1$ . (These won’t be true discontinuities, but will be smooth step-like functions achieved with erfs.)

There will be two important input parameters in this system:

1. The stiffness,

$$\mathcal{S} = \frac{N_t^2}{f_{\text{conv}}^2}, \quad (5)$$

which is the ratio of the buoyancy frequency (in the stable layer) to the square convective frequency.

2.  $\mathcal{P}$ , a parameter which sets the penetration depth.  $\mathcal{P}$  determines what the magnitude of the *negative* convective flux would be in an adiabatic penetrative layer with  $k = k_t$ . We will define  $\mathcal{P} = -F_{\text{conv}}/F_{\text{conv,rz}}$ , and our expectation is that we get a lot of convective penetration when  $\mathcal{P} \gg 1$  and none when  $\mathcal{P} \ll 1$ .

In addition to these parameters, the magnitude of the heating,  $Q$  and the vertical extent of the heating layer,  $\delta_H$ , must be specified as they set  $F_{\text{conv}} = Q\delta_H$ . We will choose  $Q = 1$  and  $\delta_H = 0.2$  so that  $F_{\text{conv}} = 0.2$ ; we will furthermore choose and  $F_{\text{bot}} = \zeta F_{\text{conv}}$ , where  $\zeta$  is some arbitrary scalar that sets how much smaller  $k$  is in the cz than the RZ; we’ll set  $\zeta = 10^{-3}$  for now.

Under these choices, the system is determined by five equations,

1. At some point, the adiabatic gradient is equal to the radiative gradient,

$$k_{\text{ad}} \nabla_{\text{ad}} = F_{\text{tot}}. \quad (6)$$

2. at  $z = 0$ , the base of the CZ, the adiabatic temperature gradient is the radiative gradient,  $\nabla_{\text{ad}} = \nabla_{\text{rad}}$ , and carries  $F_{\text{bot}}$ ,

$$k_b \nabla_{\text{ad}} = F_{\text{bot}} \quad (7)$$

3. The radiative gradient can carry the flux in the RZ,

$$k_t \nabla_{\text{rad,t}} = F_{\text{tot}} \quad (8)$$

4. Assuming  $\nabla T = -\nabla_{\text{ad}}$  everywhere, the convective flux in the top layer is  $F_{\text{conv},t} = F_{\text{conv}} - \Delta k \nabla_{\text{ad}}$ , where  $F_{\text{conv}} = Q\delta_H$  and  $\Delta k = k_t - k_b$ . Thus, definitionally,

$$\mathcal{P} = -\frac{F_{\text{conv}}}{F_{\text{conv},t}} = \left( \frac{\Delta k \nabla_{\text{ad}}}{Q\delta_H} - 1 \right)^{-1}. \quad (9)$$

5. Defining  $f_{\text{conv}}^2 \approx Q$  and  $N^2 \approx -(\nabla_{\text{rad},t} - \nabla_{\text{ad}})$ , the stiffness gives

$$\mathcal{S} = \frac{N^2}{f_{\text{conv}}^2} = \frac{-(\nabla_{\text{rad},t} - \nabla_{\text{ad}})}{Q} = \frac{F_{\text{tot}}}{Q}(k_{\text{ad}}^{-1} - k_t^{-1}) \quad (10)$$

Solving this system of equations gives

$$k_t = \frac{\delta_H}{\mathcal{S}\mathcal{P}}, \quad k_b = k_t \frac{\zeta}{1 + \zeta + \mathcal{P}^{-1}}, \quad k_{\text{ad}} = k_t \frac{1 + \zeta}{1 + \zeta + \mathcal{P}^{-1}}, \quad (11)$$

$$\nabla_{\text{ad}} = Q\mathcal{S}\mathcal{P}(1 + \zeta + \mathcal{P}^{-1}), \quad \nabla_{\text{rad}} = Q\mathcal{S}\mathcal{P}(1 + \zeta). \quad (12)$$

Just to be safe, I'm going to offset the internal heating from the bottom boundary. We wouldn't need to do this if we didn't have a bottom, impenetrable boundary condition with a viscous boundary layer. But, since  $w \rightarrow 0$  at the bottom boundary, I don't want to inject heating into the domain somewhere where it must be carried by a superadiabatic temperature gradient (I explicitly don't want to study boundary-driven convection). So

$$Q(z) = \begin{cases} 0 & z < 0.1 \\ Q & 0.1 \leq z < 0.1 + \delta_H, \\ 0 & \text{elsewhere} \end{cases} \quad (13)$$

We then choose  $T_0$  to satisfy

$$\partial_z T_0 = - \begin{cases} \nabla_{\text{ad}} & z \leq 1 \\ \nabla_{\text{rad}} & z > 1 \end{cases} \quad (14)$$

(again, perhaps not perfectly this, but with smooth transitions). And we're off to the races.
